The scientific standing of psychoanalysis

Mark Solms

‘Psychoanalysis still represents the most coherent and intellectually satisfying view of the mind’ (Kandel, 1999)

Speaking in my capacity as Director of the Science Department of APsaA, my aim in this presentation is to propose what we psychoanalysts may consider to be the core scientific claims of our discipline today. This scientific stock-taking is necessary due to widespread misconceptions among the public, and disagreements among ourselves regarding specialist details, which obscure the bigger picture upon which we can all agree. Agreement on our core claims enables us to defend them against the prejudice that psychoanalysis is not ‘evidence-based’.

I want to address three questions: (1) how does the emotional mind work, in health and disease?; (2) on this basis, what does psychoanalytic treatment aim to achieve?; and (3) does it work?

My arguments will be: (1) psychoanalysis rests upon three core claims about the human mind that were once considered controversial but which are now widely accepted in neighbouring disciplines; (2) the clinical methods that psychoanalysts use to relieve mental suffering flow directly from these core claims, and are consistent with current scientific understanding of how the brain changes; (3) it is therefore not surprising that psychoanalytic therapy achieves good outcomes – at least as good as, and in some respects better than, other evidence-based treatments in psychiatry today.

I will now review these three arguments in turn:

1. **Our three core claims about the mind** are the following: (a) the human infant is not a blank slate; *like all other species, we are born with a set of innate needs*; (b) *the main task of mental development is to learn how to meet these needs in the world*, which implies that mental disorder arises from failures to achieve this task; (c) *most of our ways of meeting our needs are effected unconsciously*, which requires us to bring them to consciousness once more in order to change them.

   (a) **The human infant is not a blank slate; like all other species, we are born with a set of innate needs.** These needs (‘demands upon the mind to perform work’, as Freud (1915) called them -- his “id”) are felt and expressed as emotions. That is why emotion is so important in psychoanalysis. The basic (hard-wired) emotions release instinctual behaviours, which are innate predictions as to what we must do in order to meet our needs (e.g., cry, search, freeze, flee, attack). Universal agreement about the number of innate needs in the human brain has not been achieved,1 but most mainstream taxonomies (e.g. Panksepp 1998) include the following.2

---

1 The taxonomy of human instincts is an empirical question; it does not affect the basic claim that we are born with a set of innate needs, which are felt as emotions.

2 Here I am focusing on emotional needs -- which are felt as separation distress, rage, etc -- not bodily drives -- which are felt as hunger, thirst, etc -- or sensory affects -- which are felt as pain, disgust, etc.
• We need to engage with the world -- since all our biological appetites (including bodily needs like hunger and thirst) can only be met there. This is a foraging or 'wanting' instinct. It is felt as interest, curiosity and the like. (It coincides roughly but not completely with Freud's concept of "libido").
• We need to find sexual partners. This is felt as lust. This instinct is sexually dimorphic (on average) but male and female inclinations exist in both genders.
• We need to escape dangerous situations. This is fear.
• We need to destroy frustrating objects (things that get between us and satisfaction of our needs). This is rage.
• We need to attach to caregivers (those who look after us). Separation from attachment figures is felt as panic, and loss of them is felt as despair. (The whole of "attachment theory" relates to vicissitudes of this need.)
• We need to care for and nurture others, especially our offspring. This is the so-called 'maternal instinct', but it exists (to varying degrees) in both genders.
• We need to play. This need is not as frivolous as it appears; play is the medium through which social hierarchies are formed ('pecking order') and in-group and out-group boundaries are maintained.

(b) The main task of mental development is to learn how to meet our needs in the world. We do not learn for its own sake; we do so in order to establish optimal predictions as to how our needs can be met in a given environment. (This is what Freud called "ego" development.) This is necessary because even innate predictions have to be reconciled with actual experiences. Evolution predicts how we should behave in, say, dangerous situations, but it cannot predict all possible dangers (e.g., electrical sockets); each individual has to learn what to fear. This typically happens during critical periods in early childhood, when we are not best equipped to deal with the fact that innate predictions often conflict with one another (e.g., attachment vs rage, curiosity vs fear). We therefore need to learn compromises, and we must find indirect ways of meeting our needs. This often involves substitute-formation (e.g., kicking the cat). Humans also have a large capacity for satisfying their needs in imaginary and symbolic ways. -- It is crucial to recognise that successful predictions entail successful emotion regulation, and vice-versa. This is because our needs are felt as emotions; thus successful avoidance of attack reduces fear, successful reunion after separation reduces panic, etc, whereas unsuccessful attempts at avoidance or reunion result in persistence of fear or panic, etc.

(c) Most of our cognitive predictions (i.e., ways of meeting our needs) are effected unconsciously. Consciousness ('working memory') is an extremely limited resource, so there is enormous pressure to automatise learnt solutions to life's problems (for review see Bargh & Chartrand 1999, who conclude that only 5% of our goal-directed actions are conscious). Innate predictions are effected automatically from the outset, as are the predictions acquired in the first years of life, before the conscious ('declarative') memory systems mature. Multiple unconscious ('non-declarative') memory systems exist, such as 'procedural' and 'emotional' memory, which operate according to different rules. Not only successful predictions are automatized. Sometimes a child has to make the best of a bad job in order to focus on the problems which it can solve. Illegitimacy or

---

3 The fact that we can only meet our needs by engaging with others is why life is difficult. You cannot successfully copulate with yourself, attach to yourself, etc, although this does not stop us from trying! (The psychoanalytic theory of "narcissism" arises from these simple facts.)
4 This is why childhood, and the quality of parental guidance, are so important in psychoanalysis.
prematurely automatized predictions are called “the repressed”. In order for automatized predictions to be revised and updated, they need to be ‘reconsolidated’ (Nader et al 2000, Sara 2000, Tronson & Taylor 2007); that is, they need to be entered consciousness again, in order for the long-term traces to become labile once more. This is difficult to achieve, not least because most procedural memories are ‘hard to learn and hard to forget’ and some emotional memories – which can be acquired through just a single exposure -- appear to be indelible, but also because the essential mechanism of repression entails resistance to reconsolidation of automatized solutions to our insoluble problems.

2. My second argument is that the clinical methods that psychoanalysts use to relieve mental suffering flow from the above claims, which are consistent with current understanding of how the brain changes:

(a) Psychological patients suffer mainly from feelings. The essential difference between psychoanalytic and psychopharmacological methods of treatment is that we believe feelings mean something. Specifically, feelings represent unsatisfied needs. (Thus, a patient suffering from panic is afraid of losing something, a patient suffering from rage is frustrated by something, etc.) This truism applies regardless of aetiological factors; even if one person is constitutionally more fearful, say, than the next, their fear still means something. To be clear: emotional disorders entail unsuccessful attempts to satisfy needs.

(b) The main purpose of psychological treatment, then, is to help patients learn better (more effective) ways of meeting their needs. This, in turn, leads to better emotion regulation. The psychopharmacological approach, by contrast, suppresses unwanted feelings. We do not believe that drugs which suppress feelings can cure emotional disorder; drugs are symptomatic (not causal) treatments. To cure an emotional disorder, the patient’s failure to meet their underlying need/s must be addressed, since this is what is causing their symptoms. However, symptom relief is sometimes necessary before patients become accessible to psychological treatment, since most forms of psychotherapy require collaborative work between patient and therapist (see below).

(c) Psychoanalytical therapy differs from other forms of psychotherapy in that it aims to reconsolidate deeply automatized predictions. This is necessary for the reasons outlined above. Psychoanalytic technique5 therefore focuses on:

- Identifying the dominant emotions (which are consciously felt but not necessarily recognized as belonging to the self, etc).
- These emotions reveal the meaning of the symptom. That is, they lead the way to the (unsuccessful) automatized predictions that gave rise to the feelings.
- The pathogenic predictions cannot be remembered directly for the very reason that they are automatized (i.e. unconscious). Therefore, the analyst identifies them indirectly, by bringing to awareness the repetitive patterns of behaviour derived from them.
- Reconsolidation is thus achieved through reactivation of long-term traces via their derivatives in the present situation (this is called “transference” interpretation).
- Such reconsolidation is nevertheless difficult to achieve, mainly due to the ways in which non-declarative memory systems work (they are ‘hard to learn, hard to

5 See Blagys & Hilsenroth 2000.
3. My third argument is that psychoanalytic therapy achieves good outcomes – at least as good as, and in some respects better than, other evidence-based treatments in psychiatry today:

(a) *Psychotherapy in general is a highly effective form of treatment.* Meta-analyses of psychotherapy outcome studies typically reveal effect sizes of between 0.73 and 0.85. (An effect size of 1.0 means that the average treated patient is one standard deviation healthier than the average untreated patient.) An effect size of 0.8 is considered a large effect in medical research, an effect size of 0.5 is considered moderate, and an effect size of 0.2 is considered small. To put the efficacy of psychotherapy into perspective, recent antidepressant medications achieve effect sizes of between 0.24 (tricyclics) and 0.31 (SSRIs). The changes brought about by psychotherapy, no less than drug therapy, are of course visualizable with brain imaging (see Be Auregard 2014).

(b) *Psychoanalytic psychotherapy is equally effective* as other forms of psychotherapy (e.g. CBT) but there is evidence to suggest that the effects last longer -- and even increase -- after the end of the treatment. Shedler’s authoritative (2010) review of all psychoanalytic outcome studies to date reported effect sizes of between 0.78 and 1.46, even for diluted and truncated forms of psychoanalytic therapy. An especially methodologically rigorous meta-analysis (Abbass et al 2006) yielded an overall effect size of 0.97 for general symptom improvement with psychoanalytic therapy. The effect size increased to 1.51 when the patients were assessed at long-term follow-up, whereas the effects of other forms of psychotherapy (like CBT) tend to decay. A more recent meta-analysis by Abbass et al (2014) yielded an overall effect size of 0.71 and the finding of maintained and increased effects at follow-up was reconfirmed. The consistent trend toward larger effect sizes at follow-up suggests that psychoanalytic therapy sets in motion processes of change that continue even after therapy has ended (cf. “working through”).

(c) The therapeutic techniques that predict best treatment outcomes, regardless of the form of psychotherapy, make good sense in relation to the psychodynamic mechanisms outlined above. These techniques are (Blagys & Hilsenroth 2000):

- unstructured, open-ended dialogue between patient and therapist
- identifying recurring themes in the patient’s experience
- linking the patient’s feelings and perceptions to past experiences
- drawing attention to feelings regarded by the patient as unacceptable
- pointing out ways in which the patient avoids them
- focusing on the here-and-now therapy relationship
- drawing connections between the therapy relationship and other relationships

It is highly instructive to note that these techniques lead to the best treatment outcomes, regardless of the ‘brand’ of therapy that the clinician espouses. In other words, these same techniques (or at least a subset of them; see Hayes et al 1996) predict optimal treatment outcomes in CBT too, even if the therapist believes otherwise.

---

(d) It is therefore perhaps not surprising that psychotherapists, irrespective of their stated theoretical orientation, tend to choose psychoanalytic psychotherapy for themselves! (Norcross 2005)
